Received 16 March 2007; revised 28 August 2007; accepted 21 September 2007; published 13 November 2007.

[1] A consistent time series of stratospheric inorganic chlorine Cl\textsubscript{i} from 1991 to present is formed using space-borne observations together with neural networks. A neural network is first used to account for inter-instrument biases in HCl observations. A second neural network is used to learn the abundance of Cl\textsubscript{i} as a function of HCl and CH\textsubscript{4}, and to form a time series using available HCl and CH\textsubscript{4} measurements. The estimates of Cl\textsubscript{i} are broadly consistent with calculations based on tracer fractional releases and previous estimates of stratospheric age of air. These new estimates of Cl\textsubscript{i} provide a critical test for global models, which exhibit significant differences in predicted Cl\textsubscript{i} and ozone recovery. Citation: Lary, D. J., D. W. Waugh, A. R. Douglass, R. S. Stolarski, P. A. Newman, and H. Mussa (2007), Variations in stratospheric inorganic chlorine between 1991 and 2006, Geophys. Res. Lett., 34, L21811, doi:10.1029/2007GL030053.

1. Introduction

[2] Knowledge of the distribution of inorganic chlorine Cl\textsubscript{i} in the stratosphere is needed to attribute changes in stratospheric ozone to changes in halogens, and to assess the realism of chemistry-climate models [Eyring et al., 2006; Eyring et al., 2007]. However, there are limited direct observations of Cl\textsubscript{i}. Simultaneous measurements of the major inorganic chlorine species are rare [Zander et al., 1992; Gunson et al., 1994; Bonne et al., 2000; Nassar et al., 2006]. In the upper stratosphere, Cl\textsubscript{i} can be inferred from HCl alone [e.g., Anderson et al., 2000; Froidevaux et al., 2006b].

[3] Here we combine observations from several space-borne instruments using neural networks [Lary and Mussa, 2004] to produce a time series for Cl\textsubscript{i}. A neural network is used to characterize differences among various HCl measurements, and to perform an inter-instrument bias correction. Measurements from several different instruments are used in this analysis. These instruments, together with temporal coverage and measurement uncertainties, are listed in Table 1. The HALOE uncertainties are only estimates of random error and do not include any indications of overall accuracy. All instruments provide measurements through the depth of the stratosphere. A second neural network is used to infer Cl\textsubscript{i} from these corrected HCl measurements and measurements of CH\textsubscript{4}.

[4] Sections 2 and 3 describe the HCl and Cl\textsubscript{i} intercomparisons. Section 4 presents a summary.

2. HCl Intercomparison

[5] We first compare measurements of HCl from the different instruments listed in Table 1. Comparisons are made in equivalent PV latitude - potential temperature coordinates [Schoeberl et al., 1989; Proffitt et al., 1989; Lait et al., 1990; Douglass et al., 1990; Lary et al., 1995; Schoeberl et al., 2000] to extend the effective latitudinal coverage of the measurements and identify contemporaneous measurements in similar air masses.

[6] The Halogen Occultation Experiment (HALOE) provides the longest record of space based HCl observations. Figure 1 compares HALOE HCl with HCl observations from (1) the Atmospheric Trace Molecule Spectroscopy Experiment (ATMOS), (2) the Atmospheric Chemistry Experiment (ACE), and (3) the Microwave Limb Sounder (MLS). In these plots each point is the median HCl observation made by the instrument during each month for 30 equivalent latitude bins from pole to pole and 25 potential temperature bins from the 300–2500 K potential temperature surfaces.

[7] For each of these bins we only use data in the range where the supplied quality flags show it suitable for scientific use. For each bin, we characterize the median observation uncertainty and the representativeness uncertainty. The representativeness is a measure of the spatial variability over the bin, in our case characterized by the average deviation of the observations in the bin. The average deviation is a measure of the width of the probability distribution of observations. Unlike the standard deviation, the average deviation is not strongly influenced by a few outliers. Each of these uncertainties are used later in Figures 2 and 3.

[8] A consistent picture is seen in these plots: HALOE HCl measurements are lower than those from the other instruments. The slopes of the linear fits (relative scaling) are 1.05 for the HALOE-ATMOS comparison, 1.09 for the HALOE-MLS, and 1.18 for the HALOE-ACE. The offsets are apparent at the 525 K isentropic surface and above. Previous comparisons among HCl datasets reveal a similar bias for HALOE [Russell et al., 1996; McHugh et al., 2005; Froidevaux et al., 2006a]. ACE and MLS HCl measurements are in much better agreement (Figure 1d). Note, all measurements agree within the stated observational uncertainties summarized in Table 1.

[9] To combine the above HCl measurements to form a continuous time series of HCl (and then Cl\textsubscript{i}) from 1991 to 2006 it is necessary to account for the biases between data
sets. A neural network is used to learn the mapping from one set of measurements onto another as a function of equivalent latitude and potential temperature [Lary and Mussa, 2004]. We consider two cases. In one case ACE HCl is taken as the reference and the HALOE and Aura HCl observations are adjusted to agree with ACE HCl. In the other case HALOE HCl is taken as the reference and the Aura and ACE HCl observations are adjusted to agree with HALOE HCl. In both cases we use equivalent latitude and potential temperature to produce average profiles. The purpose of the mapping is simply to learn the bias as a function of location, not to imply which instrument is correct.

The precision of the correction using the neural network mapping is of the order of $0.3 \text{ ppbv}$, as seen in Figure 1e which shows the results when HALOE HCl measurements have been mapped into ACE measurements. The mapping has removed the bias between the measurements and has also straightened out the ‘wiggles’ in Figure 1c, i.e., the neural network has learned the equivalent PV latitude and potential temperature dependence of the bias between HALOE and MLS. The inter-instrument offsets are not constant in space or time, and are not a simple function of $\text{Cl}_y$.

3. Inorganic Chlorine $\text{Cl}_y$

[11] To a first approximation $\text{Cl}_y \approx \text{HCl} + \text{ClONO}_2 + \text{ClO} + \text{HOCl}$ [Brasseur and Solomon, 1987]. However, observations of ClONO2, ClO and HOCl are much more limited than those of HCl (for example, there is no ACE ClO product available above 29.5 km). As shown in Table 1, ClONO2 measurements have been made by CLAES (1991–1993), ATMOS (1992–1994), CRISTA (1994, 1998), and ACE (2004–present). ClO measurements have been made by the UARS MLS (1991–1999), aircraft, MkIV, ACE, and Aura MLS (2004–present). HOCl measurements have been made by ACE and Aura MLS.

*The uncertainties given are the median values calculated for each level 2 measurement profile and its uncertainty (both in mixing ratio) for all the observations made. The uncertainties are larger than usually quoted for MLS ClO because they reflect the single profile precision, which is improved by temporal and/or spatial averaging. The HALOE uncertainties are only estimates of random error and do not include any indications of overall accuracy.

Figure 1. (a, b, c, d) Scatter plots of all contemporaneous observations of HCl made by HALOE, ATMOS, ACE, and MLS Aura. In Figure 1a, 1b, and 1c HALOE is shown on the x-axis. (e) As in Figure 1c except that it uses the neural network ‘adjusted’ HALOE HCl values. (f) The validation scatter diagram of the neural network estimate of Cl$_y$, HCl + ClONO$_2$ + ClO + HOCl versus the actual Cl$_y$ for a totally independent data sample not used in training the neural network.
Because of the limited temporal coverage of ClONO2 measurements it is not possible to form a continuous time series of Cl\textsubscript{y} by combining HCl, ClONO2, HOCl, and ClO. However, it is possible to form a time series of Cl\textsubscript{y} using a neural network trained by the available Cl\textsubscript{y} observations. There are sufficient observations of ClONO2, ClO and HOCl from aircraft, ACE, ATMOS, CLAES, CRISTA, MkIV and MLS to train a neural network to learn the Cl\textsubscript{y} abundance as a function of HCl and CH\textsubscript{4}, for each of which there is a long, near-continuous, time series of measurements. The resulting reconstruction reproduces an independent validation dataset faithfully with a correlation coefficient of 0.99, and provides a scatter diagram with a slope very close to one for the observed Cl\textsubscript{y} plotted against the neural network inferred Cl\textsubscript{y}, see Figure 1f.

The inputs to the neural network that estimates Cl\textsubscript{y} are HCl, CH\textsubscript{4}, equivalent latitude and potential temperature. HCl is used because it is continuously observed from the launch of UARS to the present and is typically the major Cl\textsubscript{y} reservoir. CH\textsubscript{4} is used because it is continuously observed from the launch of UARS to the present and, as a long-lived tracer, it is well correlated with Cl\textsubscript{y}. Potential temperature and equivalent latitude are used because the correlation between long-lived tracers such as CH\textsubscript{4} and Cl\textsubscript{y} is a strong function of altitude and a weak function of latitude [Lary and Mussa, 2004]. When we do the training we randomly split our training dataset into three portions of 80%, 10% and 10%. The 80% is used to train the neural network weights. This training is iterative and on each iteration we evaluate the current RMS error of the neural network. The RMS error is calculated by using the second 10% of the data that was not used in the training. We use the RMS error and the way it changes with training iteration (epoch) to determine the convergence of our training. When the training is complete, we use the final 10% as a validation dataset. This 10% of the data was randomly chosen and not used in either the training or RMS evaluation. We only use the neural network if the validation scatter diagram, which plots the actual data from validation portion against the neural network estimate, yields a straight line graph with a slope of 1. This is a stringent and independent validation. The validation is global as the data was randomly selected.
over all temporal and spatial data points available. Several training strategies were examined, the one described included the most species over the longest time period.

[14] Figure 2 shows how Cl\textsubscript{y} profiles estimated by the neural network agree directly with observed Cl\textsubscript{y} for October 2005. In each case the shaded range represents the total uncertainty associated with the Cl\textsubscript{y} estimate. The HCl bias between HALOE and ACE (the difference between the green and blue lines) is a major uncertainty. To enable us to compare these neural network fits to observations, the red crosses with error bars show the observed Cl\textsubscript{y} ≈ HCl + ClO\textsubscript{2} + ClO + HOC\textsubscript{1} based on the available ACE data, and there is good agreement between these observations and the neural network calibrated to ACE data (note ACE ClO is not available above 30 km).

[15] The distribution of Cl\textsubscript{y} is expected to change between 1991 and 2006 as the abundances of its source gases have changed. Figure 3 shows the time-series of Cl\textsubscript{y} for the 525 K isentropic surface (∼20 km) and the 800 K isentropic surface (∼30 km), for three different equivalent latitudes. The upper limit of each light shaded range corresponds to the estimate of Cl\textsubscript{y} for the neural network calibrated to agree with ACE v2.2 HCl, and the lower limit to the estimate of Cl\textsubscript{y} for the neural network calibrated to agree with HALOE v19 HCl. The dark shading in Figure 3 shows the total uncertainty, the root mean square of the observational uncertainty, the representativeness uncertainty (the variability over the analysis grid cell PV-theta bin), the inter-instrument bias in HCl, the uncertainty associated with the neural network inter-instrument correction, and the uncertainty associated with the neural network inference of Cl\textsubscript{y} from HCl and CH\textsubscript{4}. We estimate the uncertainty due to the neural network fitting using the neural network validation scatter diagram. This scatter diagram shows a cloud of finite width about the 1:1 line. We use the width of the cloud as an estimate of the uncertainty associated with the neural network fitting.

[16] The variation in Cl\textsubscript{y} estimates between the two cases depends on latitude, altitude and season and is typically ≤0.4 ppbv at 800 K. There is a general tendency of Cl\textsubscript{y} to increase in the 1990s, peak around 2000, and then slowly decrease. This is consistent with our expectations based on the tropospheric abundance of chlorine containing source gases. The Cl\textsubscript{y} time-series shown in Figure 3 constitutes a useful test for model simulations. The variation in simulated Cl\textsubscript{y} from the chemistry-climate models used in the recent [World Meteorological Organization (WMO), 2006] report is much greater than the above uncertainty in Cl\textsubscript{y}. For example, the simulated peak annual-mean Cl\textsubscript{y} for north mid-latitudes varies from 0.8 to 2.8 ppb [Eyring et al., 2007]. We have represented this uncertainty by the light shading.

[17] The estimates of Cl\textsubscript{y} produced are broadly consistent with calculations based on tracer fractional releases [Newman et al., 2006] and previous estimates of stratospheric age of air. Observations show that at 20 km the mean age increases from around 2 years in the tropics to around 4 years at high latitudes (60°N), with a similar gradient at 30 km but older ages by around 2 years [Waugh and Hall, 2002]. The curves in Figure 3 show calculations of Cl\textsubscript{y} for a range of values of the mean age of air, and the ages that are required to match the observed Cl\textsubscript{y} are consistent with the observations of the mean age.

4. Summary

[18] A consistent time series of stratospheric Cl\textsubscript{y} from 1991 to present has been formed using available space-borne observations. Here we used neural networks to inter-calibrate HCl measurements from different instruments, and to estimate Cl\textsubscript{y} from observations of HCl and CH\textsubscript{4}. These estimates of Cl\textsubscript{y} peaked in the late 1990s and have begun to decline as expected from tropospheric measurements of source gases and troposphere to stratosphere transport times. Furthermore, the estimates of Cl\textsubscript{y} are consistent with calculations based on tracer fractional releases and age of air [Newman et al., 2006]. The Cl\textsubscript{y} time-series formed here is an important benchmark for models being used to simulate the recovery of the ozone hole. Although there is uncertainty in the estimates of Cl\textsubscript{y} primarily due to biases in HCl measurements, this uncertainty is small compared with the range of model predictions shown in the recent [WMO, 2006] report.

[19] Acknowledgments. It is a pleasure to acknowledge NASA for research funding (Aura Validation and MAP), Lucien Froidevaux and the Aura MLS team for their data, the ACE team, Peter Bernath, Chris Boone, and Kaley Walker for their data, the HALOE team and Ellis Remsberg for their data, and the ATREOS team for their data. The ACE mission is funded primarily by the Canadian Space Agency.
